WILLAGE: A Two-Tiered Peer-to-Peer Resource Sharing Platform for Wireless Mesh Community Networks

Laura Galluccio* Giacomo Morabito* Sergio Palazzo* Marco Pellegrini†
M. Elena Renda† Paolo Santi†

Abstract

The success of experiences such as Seattle and Houston Wireless has attracted the attention on the so called *wireless mesh community networks*. These are wireless multihop networks spontaneously deployed by users willing to share communication resources. Due to the *community* spirit characterizing such networks, it is likely that users will be willing to share other resources besides communication resources, such as data, images, music, movies, disk quotas for distributed backup, and so on. In other words, it is expected that peer-to-peer applications will be deployed in such type of networks. In this paper we propose WILLAGE, a platform for resource localization in wireless mesh community networks with mobile users. The platform is based on a two-tiered architecture: resources are made available at the lower tier, which is composed of mobile terminals, whereas information on their localization is managed at the upper layer, which is composed of wireless mesh routers. We also introduce *Georoy*, an algorithm for the efficient retrieval of the information on resource localization based on the *Viceroy* algorithm. Simulation results show that WILLAGE achieves its goal of enabling efficient and scalable peer-to-peer resource sharing in wireless mesh community networks.

Keywords: Wireless mesh networks, community networks, peer-to-peer applications, resource localization, scalability.

1 Introduction

Wireless mesh networks are a promising area for the deployment of new wireless communication and networking technologies [1, 3]. Differently from traditional, infrastructure-less ad hoc networks, mesh networks are composed of two classes of nodes: *mesh clients* and *mesh routers*. Since mesh routers typically have minimal mobility and are not energy constrained, they can be used to provide a wireless communication infrastructure to the mesh clients. Consequently, the functionalities required on the mesh clients can be significantly simplified with respect to traditional ad hoc networks, potentially resulting in better network efficiency and scalability.

†Istituto di Informatica e Telematica del CNR, Pisa, Italy

One of the possible application scenarios for wireless mesh networks is the realization of *wireless community networks*, which are becoming increasingly popular since the advent of cheap wireless technologies such as IEEE 802.11. Following the success of experiences such as Seattle and Houston Wireless [10, 20], several wireless community networks are spontaneously being created all over the world. Currently, more than 300 wireless communities can be counted worldwide [23], and this number is constantly increasing. Actually, we can expect that the standardization activity which is currently focusing on wireless mesh technologies (see, e.g., the IEEE 802.11, 802.15, and 802.16 working groups) will provide a further boost to the development of wireless mesh community networks.

Although wireless community networks are becoming widespread, and several applications for this type of networks are envisioned, so far they can typically be used only to share communication resources, such as broadband Internet access. However, given the *community* spirit of such networks, it is expected that users will be willing to share other resources, such as data, images, music, movies, disk quotas for distributed backup, etc. It is therefore likely that peer-to-peer applications will play a fundamental role in enriching the services offered by community networks.

In this paper we consider one of the major problems to be solved in peer-to-peer applications, i.e., efficiently finding the resources currently available in the network, in the context of wireless mesh community networks. To address this problem, we propose a two-tier peer-to-peer platform called WILLAGE (a shorthand for Wireless-Village). We believe our proposed platform can be used as a fundamental building block in the development of community-related application services, thus contributing to the creation of a wireless village in which mobile users (the village inhabitants) use each other resources with an overall benefit to the community.

To the best of our knowledge, WILLAGE is the first peer-to-peer platform which is explicitly designed for wireless mesh networks. The emphasis in our design is on *scalability*, since we believe this will be a fundamental property of any solution tailored to wireless community networks. In fact, the coverage area of community networks is expected to increase up to an entire city area, and we envision that the number of network nodes (both clients and routers) composing the network will grow as well, up to hundreds or even thousands of nodes. As an example, around 500 wireless routers are used to provide wireless connectivity to the city of Rio Rancho, NM, USA [2].

In order to achieve our design goal, we exploit a peculiar feature of mesh networks, i.e., the existence of a wireless communication infrastructure (consisting of the wireless routers) which is available to the mesh clients. This leads to the definition of a two-tier peer-to-peer architecture, where mobile mesh clients (also called *leaf peers*) provide and use content, and mesh routers (also called *super peers*) are used to assist mesh clients in locating the requested resources. The latter task is accomplished by implementing a distributed hash table (DHT) at the super peer

level, where super peers establish a limited number of logical links towards other super peers in the network, and resource requests travel only along these logical links. We propose the Georoy algorithm (a geographic variation of the Viceroy algorithm introduced in [14]) to implement the DHT at the super peer level, and we formally prove that the set of logical links created by Georoy efficiently exploits the underlying physical wireless network. Finally, we verify through simulation that the search efficiency of Georoy (i.e., the average number of network-layer messages generated to satisfy a resource request) is as much as 7 times better than that achieved by Viceroy, and that our proposed WILLAGE platform achieves its goal of enabling efficient and scalable resource localization in wireless mesh community networks.

The rest of this paper is organized as follows. In Section 2, we present related work, and we highlight the original contributions of our paper. In Section 3, we present WILLAGE architecture, and in Section 4 we present the Georoy algorithm for implementing the DHT at the super peer level. In Section 5, we describe how Georoy can be integrated into the WILLAGE platform, and in Section 6 we present a simulation-based performance evaluation of our peer-to-peer resource sharing platform. Finally, Section 7 concludes and discusses future research directions.

2 Related work and basic idea

The problem of enabling efficient peer-to-peer (P2P) resource sharing has been widely studied in the literature, following the success of the Napster file sharing application [15]. Indeed Napster cannot be considered as a pure P2P approach, since the index of the files available in the network is maintained by a centralized server: when a new peer joins the network, it provides the catalog of the files it will to share to the centralized server, which handles also all the search requests issued by peers. Since the use of a centralized server creates a bottleneck (and unique point of failure) in the system, several later proposals adopted a distributed approach to solve the P2P resource sharing problem.

Gnutella v0.4 [6] is an example of flat, unstructured P2P network with no directory service: when a new peer joins Gnutella, it establishes a number of virtual links to other peers in the network according to a certain rule, thus forming an overlay network. When a peer receives (or issues) a search request, it first checks whether the request can be satisfied locally, otherwise it forwards the request to its neighbors in the overlay. The request is flooded in the network until its time to live (TTL) expires. Thanks to its fully distributed nature, Gnutella v0.4 displays better robustness than Napster, but the use of (limited) request flooding causes a considerable message overhead and reduces the accuracy of the search process.

In order to maintain the search efficiency provided by a directory service while not sacrificing robustness and scalability, a number of P2P approaches are based on a hierarchical organization of peers: network members are divided into a large number of peers that provide content (called

leaf peers), and into a smaller number of peers that implement local directory services and route search requests (called *super peers*). In hierarchical P2P networks, each super peer provides a centralized directory service to a subset of the leaf peers. Leaf peers are connected to one or more super peers, to which they provide their catalog of shared resources. Super peers are interconnected by a number of virtual links, thus forming an overlay network at the super peer level. Search requests originate at leaf peers and are handled by super peers: a leaf peer sends its request to the super peer(s) to which it is connected to; if it cannot be satisfied locally, the request is flooded in the super peer overlay network until its TTL (Time To Live) expires. Examples of hierarchical P2P networks are Gnutella v0.6 [7] and KaZaA [11].

In the above described P2P approaches the virtual overlay network used for searching the available resources within the network is unstructured. A number of recent proposals is aimed at improving search accuracy and efficiency by imposing a certain desirable structure to the overlay network. This is the case of approaches based on the Distributed Hash Table (DHT) abstraction: a key is assigned to each resource available in the network (e.g., by hashing the resource name), and a node ID is associated with each peer (e.g., the IP address). A certain range of keys is assigned to each peer in the system, which is responsible for answering the queries in the range. Based on its ID, a peer establishes a limited number of virtual links with other peers in the network, forming a highly structured virtual overlay network. The search process can be seen as searching a key in a (distributed) hash table, and is performed by comparing the queried key with the node ID: if the key belongs to the range managed by the node, then the query is answered and returned to the originating peer, otherwise it is forwarded to a specific neighbor in the overlay, which is chosen depending on the key value. DHT approaches differ on the structure imposed to the virtual overlay and on the mechanism used to route search requests in the overlay. For instance, CAN [17] routes along a hypercube, Chord [22] routes along a ring, Viceroy [14] is based on a butterfly network, and Tapestry [9] uses a tree. The interesting feature of DHT approaches is that queries can be correctly answered by traversing a limited number of links in the virtual overlay network (typically, $O(\log n)$ links, where n is the number of peers in the system). On the other hand, preserving this nice feature in presence of frequent peer join/leaves (as it is typically the case in P2P applications) is very challenging.

Typically, P2P systems are designed and optimized for use in wired networks (e.g., the Internet). A few recent works have considered the problem of designing and/or extending existing systems to work efficiently on wireless ad hoc networks. In these networks, many additional challenges must be faced when designing P2P applications. The main ones are related to the lack of a wired infrastructure, the unreliability of the wireless channel, and the node mobility. It has been observed that, in order to tackle these challenges, it is fundamental to carefully build the overlay network between the peers so that it closely matches the underlying physical network. In other words, it is desirable that a peer chooses as neighbors in the overlay, nodes that are not too far

in the physical network¹. This can be accomplished by using cross-layering, where the network layer and the P2P application exchange information in order to optimize system performance. An example of this approach is presented in [4], where Conti et al. present a cross-layer optimization of Gnutella². Another approach is the ORION system proposed in [12], where overlay connections (which closely match the underlying network topology) are built on-demand and maintained only as long as necessary. Other authors have focused their attention on file sharing applications, and more in particular on how to transfer files between peers once the requested file has been discovered; this task, which is typically accomplished by establishing a TCP connection in wired networks, presents several challenges in wireless mobile networks. As an example, the approach presented in [8] is based on partitioning the requested file into small packets and using Turbo coding to re-build the original file at destination.

It should be observed that, although a careful construction of the overlay helps increasing the efficiency of P2P systems for wireless ad hoc networks, the combination of node mobility, lack of infrastructure and unreliable wireless links renders the current proposals unsuitable for application in large ad hoc networks. Typically, it is assumed that the P2P network is formed by a few tenths of nodes (see [4, 12]). Hence, the design of a *scalable* P2P system for wireless ad hoc networks is still an open problem.

Another area of research which is relevant to our work is the design of storage systems for archiving data in wireless networks. As an example, in sensor networks, several authors have suggested that archival data can be stored at the sensor nodes themselves, and that a distributed indexing mechanism can be used to retrieve the data matching a certain request. An example of this is presented in GHT [16]; in this work, sensor nodes both store the archival data and implement a distributed geographic hash table. More recently, Desnoyers et al. [5] have suggested using a two-tier architecture, where the sensor nodes store the data, and a certain number of proxy nodes implements the distributed indexing mechanism. Although [5] shows similarities with our approach, it is tailored to a sensor scenario and thus energy-efficient design is the main target.

The design introduced in this paper presents several novel features. By leveraging the hierarchical architecture of wireless mesh networks, we propose WILLAGE, a hierarchical P2P system where leaf peers (the mesh clients) provide content, and super peers (the mesh routers) implement a DHT. The DHT algorithm used in WILLAGE is a variation of the Viceroy algorithm proposed in [14] based on the use of geographic information. For this reason, we call our algorithm *Georoy*. The use of a DHT allows us to implement a very efficient indexing of the available resources: every super peer maintains virtual links only to a constant number of neighbors (at most 7, in-

¹Similar concepts have been used also in traditional, Internet-based P2P designs. For instance, the approach presented in [18] builds the overlay by choosing neighbors depending on the link latency.

²The authors implement Gnutella v0.6, but they consider only super peers. So, their approach can be straightforwardly applied also to Gnutella v0.4.

dependently of the system size), and queries can be correctly answered by traversing at most $O(\log n)$ links in the virtual overlay at the super peer level, where n is the number of super peers in the network. Furthermore, our design ensures load balancing in the overlay network, and efficient maintenance of the distributed indexing mechanism in presence of super peer and leaf peer join/leaves.

Another major contribution of this paper is a theoretical analysis of the *stretch factor* of the overlay network built by Georoy. Informally speaking, the stretch factor measures how close a virtual overlay is to the topology of the underlying network (see Section 4.3 for a formal definition): the lower the stretch factor, the closer the virtual overlay to the physical underlying network. Under the assumption that super peers are distributed uniformly at random in a square region, we formally prove that the stretch factor of our system is at most $O(\sqrt{n \log n})$, showing that the virtual overlay closely matches the underlying network topology. We observe that proving similar properties in traditional, Internet-based P2P systems is very difficult, since little is known about the actual topology of the Internet. Also, no similar bound has been so far proved for wireless ad hoc or sensor networks.

We also discuss how the Georoy DHT algorithm can be integrated in the WILLAGE platform, accounting for leaf peer join/leaves, and leaf peer mobility. Finally, we present a simulation-based evaluation of Georoy's performance, which shows that our proposed algorithm achieves significantly better performance with respect to Viceroy.

3 WILLAGE platform: architecture and notation

In this section we describe the general architecture of the WILLAGE platform and introduce the notation which will be used in the rest of the paper.

The WILLAGE system architecture is shown in Figure 1. The network consists of two-tiers. The lower tier is composed of a large number of mobile user terminals in the following referred to as *leaf peers* (LP). These nodes provide the resources to be shared in the community network. The upper tier is composed of a smaller number (when compared to the number of leaf peers) of static and reliable *community nodes* which give wireless access and allow peer-to-peer resource provisioning. These nodes are supposed to be almost always active since their unavailability may cause the partition of the wireless community network. Some of these nodes can be connected to the Internet through a cabled connection but the majority are not. In the following we will refer to community nodes as *super peer* (SP) nodes.

Each LP accesses the network through a certain SP, even while moving. More specifically, the LP evaluates the signal strength for each SP in its vicinity and, at any time, connects to the one it receives the stronger signal from. Due to LP's movements, the SP they are connected to dynamically changes and occasional disconnections from the super peer overlay can also occur.

SPs are responsible for providing a distributed catalog of the available resources to the network. To this purpose, SPs compose an overlay network, realizing a distributed hash table (DHT) abstraction. The algorithm used for the management of the overlay network, called Georoy, is a variation of Viceroy [14] which takes into account geographic information, and is presented in Section 4.

Now we introduce some notation which will be used through the rest of the paper. We denote the set of leaf peers belonging to the WILLAGE by U and the set of community nodes by P . In the example reported in Figure 1, we have $U = \{1, 2, \dots, 20\}$ and $P = \{A, B, C, D, E, F\}$. Also, we denote as $p(u)$, with $p(u) \in P$, the community node selected by $u \in U$ as its responsible community node. SP $p(u)$ is called the *responsible* SP of LP u . In Figure 1, $p(1) = \dots = p(4) = A$, $p(5) = \dots = p(8) = B$, $p(9) = \dots = p(13) = C$, $p(14) = \dots = p(16) = D$, $p(17) = p(18) = E$, and $p(19) = p(20) = F$. Observe that only one responsible super peer is selected for each leaf peer, whereas several leaf peers may select the same super peer as responsible SP. Accordingly, for any $p \in P$ we denote as U_p the set of leaf peers that have selected p as their responsible SP, i.e., $U_p = \{u \in U : p(u) = p\}$. As an example, in Figure 1 we have $U_A = \{1, 2, 3, 4\}$, $U_B = \{5, 6, 7, 8\}$, $U_C = \{9, 10, 11, 12, 13\}$, $U_D = \{14, 15, 16\}$, $U_E = \{17, 18\}$, and $U_F = \{19, 20\}$.

Finally, we assume that each LP has a *Home* SP which does not change as the LP moves. For any LP $u \in U$ we denote such Home SP as $p^{(H)}(u)$; observe that in general $p^{(H)}(u) \neq p(u)$. The Home SP of u is responsible of maintaining up to date the information about the localization of u , that is its responsible SP $p(u)$, and the resources that u is willing to share.

4 The DHT algorithm

The algorithm used to implement the DHT abstraction at the super peer level is an adaptation of the Viceroy algorithm introduced in [14] to the wireless mesh network scenario. For this reason, we describe Viceroy before introducing our algorithm.

4.1 The Viceroy algorithm

In Viceroy both peer IDs and resource keys are mapped by a hashing function into to the same ID space (metric), i.e. the unit ring $[0, 1]$. Each key resides on the peer with the smallest ID larger than the key ID, i.e. the key range associated with peer p comprises all the resource keys with ID smaller than p and larger than the ID of the predecessor of p in the unit ring (see Figure 2). For simplicity, from now on we use notation p to denote both a generic peer and its ID in $[0, 1]$, and notation k to denote both a generic resource key k and its ID in $[0, 1]$. Note that two keys that are close in the ID space are located on peers which are also close in the same metric space.

Viceroy's overlay network uses both "short" and "long" range links between peers, which are

established by combining the unit ring topology with an approximation of the butterfly network³. In order to emulate the butterfly network, each peer is assigned a certain level in the network, i.e. the identity of a node in the network is composed of the pair (p, l_p) , where p is the peer ID and l_p is the level of node p in the butterfly.

ID and level assignment. When joining the network for the first time, a SP p chooses uniformly, at random, a value in the $[0, 1]$ interval, which represents its ID. Then, p randomly chooses its level l_p in the butterfly. Ideally, a peer should select its level by choosing uniformly at random a number in $\{1, \dots, \log n\}$, where n is the number of nodes currently forming the network. Since exactly computing n is virtually impossible in practice, the following procedure is used to compute an approximation of n . When joining the network, peer p first computes the distance $d(p, succ(p))$ to its successor in the unit ring by invoking a LOOKUP(p, p) operation (see below for a description of the LOOKUP procedure); then, it estimates n as $n_0 = 1/d(p, succ(p))$, and selects a level by picking uniformly at random a number in $\{1, \dots, \log n_0\}$.

While the peer ID does not change during network lifetime, the peer level can change in order to maintain a balanced subdivision of nodes into stages when new peers join/leave the network. More in particular, a peer must recompute its level when its successor in the unit ring (and, consequently, its estimation of n) changes.

Overlay construction. Viceroy's overlay network uses three types of directed links: *i*) *unit-ring links*, which connect a peer with its predecessor and its successor in the unit ring; *ii*) *level-ring links*, which are used to form a virtual bi-directional ring between the peers at the same level; and *butterfly links*, which are used to emulate a butterfly network. Butterfly links are composed of an *upward* and two *downward* links. The upward link connects peer p at level $h > 1$ to the first $(h - 1)$ -level peer after position p on the unit ring. The downward left link (the *short range* link) connects p to the first $(h + 1)$ -level peer after position p on the unit ring; the downward right link (the *long range* link) connects p to the first $(h + 1)$ -level peer after position $p + 1/2^h$ on the unit ring. Summarizing, every peer in the Viceroy overlay network has at most 7 outgoing links: 2 unit-ring links, 2 level-ring links, and 3 butterfly links (see Figure 3).

Routing. Routing in Viceroy is essentially performed by invoking a LOOKUP(x, y) function, where x is the requested key or peer ID (we recall that both resource keys and peer IDs are mapped in the same metric space), and y is the ID of the peer that invoked the function. The result of a LOOKUP(x, y) operation is the value associated with key x , or the ID of the peer that manages the key range to which x belongs (i.e. the peer with smaller ID larger than x) if no value

³The butterfly network on n nodes is a multi stage network with $\log n$ stages, where a node at stage i is connected with a limited number of nodes at stages $i - 1$ and $i + 1$. For a description of the butterfly network, see [21].

is associated with x . When the peer y at level l_y needs to retrieve key x , it initializes the current position to y and invokes the $\text{LOOKUP}(x, y)$ function. The LOOKUP request is routed in the overlay, using the following three-phased process:

1. *up to the root*: starting from y , the request is recursively forwarded upward in the butterfly - each time updating the current position - using the upward link, until level 1 is reached;
2. *traverse the tree*: the request is forwarded downward in the butterfly, using either the short or the long range link depending on whether x is at distance smaller than $1/2^h$ from the current position or not;
3. *traverse the ring*: finally, when the current peer has no downward links or it overshoots the target x , the request is forwarded using the level-ring and/or unit-ring links, until the peer s that manages the key range to which x belongs is found. Node s then returns the answer to the LOOKUP operation to y .

Overlay maintenance. A peer y in the overlay maintains the following information: (1) the ID on the unit ring (for simplicity, y); (2) the current level l_y ; (3) the connections on the unit ring, pred_y and succ_y ; (4) the connections on the level ring, pred_y^l and succ_y^l ; (5) the upward butterfly connection, succ_y^{l-1} ; and (6) the downward butterfly connections, short_y^{l+1} and long_y^{l+1} .

When a new peer y joins the network, it first selects its ID as described above. By invoking $\text{LOOKUP}(y, y)^4$, node y finds its successor succ_y in the ring, and establishes a connection to it. By exchanging information with succ_y , peer y knows the ID of its predecessor pred_y in the ring, and establishes a connection to it. Both succ_y and pred_y update their predecessor and successor link, respectively, in order to reconfigure the correct links in the unit ring. Then, succ_y transfers to y all the key-value pairs whose key is between pred_y and y . This completes the unit ring update. After that, peer y selects the current level l_y in the butterfly as described above. Then, it finds its successor succ_y^l and predecessor pred_y^l in the level ring by single-stepping on the unit ring, and establishes connections with them. The predecessor and successor links in the level ring of peers succ_y^l and pred_y^l are updated accordingly. Finally, node y establishes the butterfly links by finding succ_y^{l-1} and short_y^{l+1} (this can be done by single stepping on the unit ring), and long_y^{l+1} (this can be done by invoking $\text{LOOKUP}(y + 1/2^{l_y}, y)$, and then single stepping on the unit ring).

When peer y leaves the network, it has to remove all its established connections, notifying all neighbors in the overlay to update their links; then, y transfers its content to its successor in the unit ring.

When the current level changes (we recall that this is possible if succ_y changes), peer y has to update its level ring connections and butterfly connections, notifying the neighbors when necessary.

⁴Given the assumption of uniform ID distribution, the probability of two peers having the same ID tends to 0.

Viceroy’s properties. The following properties of Viceroy have been proved in [14], under the assumption that peer IDs and resource keys are distributed independently and uniformly at random in $[0, 1]$:

- *dilation*: If n peers are present in the network, then a LOOKUP operation is successfully completed by traversing at most $O(\log n)$ links w.h.p.⁵
- *congestion*: Let the *load* of a peer be the probability that it is involved in a LOOKUP operation on a random value generated at a random starting point, and let the *congestion* of the network be the maximum of the peer loads. If n nodes are present in the network, the expected load for any peer is $O(\log n/n)$, and the congestion is $O((\log^2 n)/n)$ w.h.p.
- *node degree*: If n peers are present in the network, then the out-degree of each node is at most 7, the expected in-degree is $O(1)$, and the largest in-degree of a peer is $O(\log n)$ w.h.p.

4.2 The Georoy algorithm

In this sub-section we show how to adapt Viceroy to the wireless mesh network scenario. First, we observe that, differently from Viceroy, in Georoy we assume a hierarchy of peers, where the lower tier of the hierarchy is composed of leaf peers that provide content to the network, and the higher tier is composed of super peers that implement a distributed index of the available resources. Hence, in Georoy we assume that identities (i.e., a peer ID in the $[0,1]$ interval, and a level in the butterfly) are assigned only to super peers. Also, a resource ID is assigned to each resource made available in the network; the resource ID is mapped into $[0,1]$ by an appropriate hash function. In Georoy, the answer to a lookup operation on a certain resource k contains the location of the resource (e.g., the addresses of the leaf peer which holds k and its Home SP) in case k is available. As explained also in Section 5.1, in WILLAGE we distinguish between two types of unavailability of the requested resource: *temporary unavailability* (i.e., the resource is available at some LP, u , in the network, but u is currently disconnected from the network), and *permanent unavailability* (i.e., none of the LPs has the requested resource). The answer to the lookup operation on k could be the address of $p^{(H)}(u)$ in case of temporary unavailability, and the ID of the super peer that manages the key range to which the key associated with k belongs in case of permanent unavailability.

In what follows, we assume that peers⁶ are distributed in a square deployment region of side s , for some constant $s > 0$, i.e. peers are located in⁷ $R = [0, s]^2$. Furthermore, we assume that peers (i.e., wireless community nodes) are aware of their position in R .

⁵W.h.p. means with probability at least $1 - c/n$, for some constant $c > 0$.

⁶From now on in this Section, the term ‘peer’ is used instead of the term ‘super peer’.

⁷The use of a right open interval is needed to simplify the definition of the ID mapping function below, and it has no practical consequences.

Our goal is to define a mechanism to assign peer IDs that preserves geographical proximity, i.e. two peers which are geographically close should be assigned close IDs in the unit ring. Preserving proximity is fundamental to achieve a close correspondence between the virtual overlay and the physical network topology.

In the Georoy algorithm, peer IDs are computed as follows. Let (x, y) denote the coordinates of peer p in R . We define a mapping function \mathcal{M} that maps a point in R into $[0, 1]$ as follows:

$$\mathcal{M}(x, y) = \begin{cases} \frac{x\Delta}{s^2} + \lfloor \frac{y}{\Delta} \rfloor \cdot \frac{\Delta}{s} & \text{if } \lfloor \frac{y}{\Delta} \rfloor \text{ is even} \\ \frac{(s-x)\Delta}{s^2} + \lfloor \frac{y}{\Delta} \rfloor \cdot \frac{\Delta}{s} & \text{if } \lfloor \frac{y}{\Delta} \rfloor \text{ is odd} \end{cases}, \quad (1)$$

where Δ is an arbitrary constant with $0 < \Delta < s$.

The intuition behind our mapping function is depicted in Figure 4: the deployment region R is divided into s/Δ sub-regions of equal area, which are defined in terms of the y coordinate. All the nodes in the same sub-region are mapped into the same segment of the unit ring, where the position of the node within the segment is determined by its x coordinate. In order to preserve proximity, the order of nodes in a segment is reversed alternately (see Figure 4).

4.3 Georoy analysis

We first show that Georoy preserves all the nice properties of the Viceroy algorithm described in Section 4.1, under the assumption that wireless community nodes are distributed independently and uniformly at random in $R = [0, s)^2$. This fact is a straightforward consequence of the following theorem, which shows that the function \mathcal{M} defined in the previous section maps a two-dimensional uniform distribution of wireless community nodes (peers) in R into a uniform distribution of peer IDs in $[0, 1]$.

Theorem 1. *Assume the wireless community nodes (peers) are distributed independently and uniformly at random in $R = [0, s)^2$; then, the peer IDs computed according to mapping \mathcal{M} are distributed independently and uniformly at random in $[0, 1]$.*

Proof. [SKETCH] Let $S_{x,d} = [x, x+d]$, with $0 \leq x \leq 1-d$ and $0 < d \leq 1$, be an arbitrary segment of length d in $[0, 1]$, and let $\mathcal{M}^{-1}(S_{x,d})$ be the set of points in R which are mapped to $S_{x,d}$ by using \mathcal{M} . It is easy to see that the area $|\mathcal{M}^{-1}(S_{x,d})|$ of the region $\mathcal{M}^{-1}(S_{x,d})$ depends only on d , i.e. segments of equal length d in $[0, 1]$ correspond to regions of the same area $|\mathcal{M}^{-1}(S_{x,d})| = f(d)$. From this fact, and from the assumption that wireless community nodes are distributed independently and uniformly at random in R , it follows that peer IDs are distributed uniformly at random in $[0, 1]$. \square

Corollary 1. *Georoy preserves the properties of dilation, congestion, and node degree of Viceroy.*

We now prove an upper bound on the stretch factor of our algorithm, which is formally defined as follows:

Definition 1 (Stretch factor). Given a query on key k , let $l(k)$ be the hop distance in the physical network between the peer at which the query is originated and the peer that manages the key range to which k belongs; furthermore, let $P(k)$ be the path traversed by the query on k in the overlay network, and let $l(P(k))$ be hop length of $P(k)$ in the physical network. The stretch factor is:

$$\text{stretch}(k) = \frac{l(P(k))}{l(k)}. \quad (2)$$

In order to prove the bound, we first show that a 1-hop path in the overlay network corresponds to a path with at most $\sqrt{\frac{n}{\log n}}$ hops in the physical network.

Lemma 1. Assume n wireless community nodes, each with transmitting range r , are distributed independently and uniformly at random in $R = [0, s]^2$. Furthermore, assume that $r = 2s\sqrt{\frac{2\log n}{n}}$. Then, a 1-hop path in the overlay network corresponds to a path with at most $\sqrt{\frac{n}{\log n}}$ hops in the physical network, a.a.s.⁸

Proof. Let us divide R into non-overlapping square cells of equal side $h = \frac{r}{2\sqrt{2}}$. The value of h is chosen so that, independently of its location, any node in a cell has a direct communication link to every other node in its cell and in the neighbor cells (horizontal, vertical, and diagonal adjacency). Thus, we have a total of $N = \frac{8s^2}{r^2}$ cells. Under the assumption that $r = 2s\sqrt{\frac{2\log n}{n}}$, we can use occupancy theory (Th. 1, pg. 5 of [13]) to prove that every cell contains at least one node a.a.s. We observe that the longest possible 1-hop path in the overlay network has length $s\sqrt{2}$ (which corresponds to the diagonal of R), and that this length is covered by traversing at most $\sqrt{N} = \sqrt{\frac{n}{\log n}}$ cells. Since every cell contains at least one node a.a.s., we have that the progress towards the destination at each hop in the physical network is of at least one cell a.a.s. This completes the proof of the lemma. \square

Note that Lemma 1 requires a condition on the transmitting range of the community nodes, which implies that the physical network must be relatively dense: every community node has $O(\log n)$ neighbors on the average. On the other hand, it is well known that this is the minimum possible density that is required to have an a.a.s. connected network under the assumption of uniformly distributed nodes (see, for instance, Th. 4.1.1, pg. 42 of [19]). Since in community networks having a connected network at the wireless router level is fundamental to provide community-related services, the condition of Lemma 1 is not stringent.

Theorem 2. Under the assumptions of Lemma 1, the stretch factor of the Georoy algorithm is $O(\sqrt{n \log n})$ a.a.s.

Proof. By the dilation property of Georoy, we have that a query traverses $O(\log n)$ hops in the overlay network w.h.p. By Lemma 1, each hop corresponds to at most $\sqrt{\frac{n}{\log n}}$ hops in the physical

⁸A.a.s. (Asymptotically Almost Surely) means with probability that converges to 1 as $n \rightarrow \infty$.

network a.a.s. Hence, a query traverses at most $O(\sqrt{n \log n})$ hops in the physical network a.a.s. The proof follows by observing that we have $l(k) \geq 1$ for any possible query on key k . \square

5 WILLAGE procedures

In this section we describe the procedures required by the WILLAGE platform to integrate the Georoy DHT algorithm in the overall system.

First, we note that at a certain time instant, t , the generic LP u may periodically pass from *active state* to inactive in the WILLAGE, and viceversa. Accordingly, a joining and a leaving procedure are required. These are described in Section 5.1. The procedures required to update the distributed resource catalog when a LP decides to share a new resource, or not to share a certain resource anymore, are presented in Section 5.2. Section 5.3 describes how *Willage* addresses the retrieval of resources. Finally, the handoff of LPs from the formerly responsible SP to another is dealt with in Section 5.4.

5.1 LP joining/leaving procedures

When a new LP u passes from the inactive to the active state, a *joining operation* is needed, i.e., node u must connect to one SP in its proximity and the information about the resources available in the distributed catalog must be updated.

To this end, LP u first listens in the wireless interface if there is any SP in its radio coverage. If at least one SP is heard, then u selects the one with the highest signal-to-noise ratio, which we denote as $p(u)$, and registers to it. Upon registering, LP u provides $p(u)$ with the list of the resources it is willing to share. Such information is maintained up to date by $p(u)$ in a local database of available resources. Accordingly, any SP, p , has a list of the resources shared by all the LPs it is responsible for, U_p .

Node u stores another list with the resources it was willing to share the last time it was connected to the network. If there are changes, i.e., leaf peer u wants to share new resources and/or does not want to share certain resources which are in the above list, then it must inform the Home SP $p^{(H)}(u)$ according to the procedure described in Section 5.2.

When a LP u leaves the community network, the list of resources available in the network has to be updated. To this purpose, node u notifies its responsible SP, $p(u)$, before leaving the network, and $p(u)$ puts the resources shared by u in *park mode* through an appropriate tagging of the entry in its local database. Also the Home SP, $p^{(H)}(u)$, must be informed that u is leaving the network so that it puts in the *park mode* the resources shared by u .

As a consequence, if u joins again the same SP, the only operation required is to move the resources shared by u in the *available mode* through a de-tagging of the relevant entries of the local resource database in $p(u)$ and in the catalog stored at $p^{(H)}(u)$.

In this way the signaling in the network is maintained at a minimum level. Resources that are in *park mode* for a time interval longer than a given threshold are removed from the local resource database, and considered as no longer available. The IDs of these resources are notified by $p^{(H)}(u)$ to the SPs that manage the corresponding key ranges, so that they can decide whether to remove the corresponding resource ID from the distributed catalog (according to whether the same resource has re-appeared or not in another part of the network).

Note that a LP u can also detach from the network without notifying its responsible SP. Such event can be detected by the network as follows. If for a certain time interval, τ_D , the SP $p(u)$ does not receive any query from u , then it sends a beacon to u . If $p(u)$ does not receive any answer from u within a certain time, it labels the resources shared by LP u as in *park mode* and informs $p^{(H)}(u)$.

5.2 Insertion/removal of resources to/from the distributed catalog

Suppose that LP u wants to share a new resource in the WILLAGE. There are two cases:

- a $p(u) = p^{(H)}(u)$. In this case, node u informs node $p(u)$. This node evaluates the key k identifying the new resource and forwards all information required to localize k to the SP which is responsible of managing the corresponding key range.
- b $p(u) \neq p^{(H)}(u)$. In this case, node u informs node $p(u)$, which inserts the new resource in the catalog of the locally available resources and then informs $p^{(H)}(u)$. The latter next updates the distributed catalog as in the previous case.

Observe that in case b) the utilization of the Home SP requires a further step, i.e., to inform node $p^{(H)}(u)$. Although this produces some overhead, the Home SP mechanism achieves better performance in case of LP mobility, as will be described in Section 5.4 and confirmed by the simulation results shown in Section 6.

Similar procedures are executed when a node is not anymore willing to share a certain resource.

5.3 Information retrieval

Search requests are issued at the lower tier, and are routed in the overlay at the upper tier. When a LP u issues a request for a certain resource, it forwards such request to its SP $p(u)$. The SP $p(u)$ first checks whether the request can be satisfied locally using the local available resources database⁹. If the request cannot be satisfied locally, i.e., the corresponding resource is not stored by any of the LP belonging to $U_{p(u)}$, then node $p(u)$ initiates a search in the overlay network as

⁹In a follow up paper, we will address the problem of having multiple copies of the same resource in the network labelled with different keys. Moreover, we will also deal with the problem of multiple copies of the same resource characterized by different reliability levels so that a priority choice can be done.

described in Section 4.2. Let v denote the LP storing the requested resource. The result of the algorithm is the identifier of the Home SP of v , that is $p^{(H)}(v)$.

The request will thus be forwarded towards $p^{(H)}(v)$, which stores information about the location of v . If the resource is available the requesting node u is informed about the identity and position of v , i.e., its address and responsible SP. If the resource is currently in *park mode*, the SP $p^{(H)}(v)$ informs node u that the requested resource is currently not available and u can decide whether to wait until the resource becomes available or not. In the former case, SP $p^{(H)}(v)$ informs u when the resource is available again and the resource transfer can begin¹⁰.

If the LP v moves or switches off during the resource transfer, the download stops and a new resource request procedure has to be initiated. When the resource is found again, download can be completed. In this context, fragmentation mechanisms could be used so that download of only the missing fragments is required, thus increasing efficiency.

Finally, if the requesting LP, u , moves or switches off during the resource transfer, the download stops and is restored when u becomes available again.

5.4 LP handoff management

Suppose that a certain LP u , which was formerly associated with SP p' , migrates in the coverage area of another SP, p'' . In this case the following operations are required: (i) informing node $p^{(H)}(u)$ that from now on $p(u) = p''$; (ii) deleting the resources stored by u from the catalog of the resources locally available at p' ; (iii) inserting the resources stored by u into the catalog of the resources locally available at p'' ; and (iv) informing all the LPs that are currently downloading resources from u , if any, that this node has moved to another position.

Observe that the use of the Home SP mechanism increases efficiency significantly when handoff occurs. In fact, besides local signaling between the leaf peer u and the past and current responsible SPs, p' and p'' , only a location update must be sent to the Home SP, $p^{(H)}(u)$. Instead, if the Home SP mechanism was not used, the location update should have to be transferred to all SPs that contain the location information concerning node u .

6 Performance evaluation

We consider a wireless mesh community network organized into two-tiers consisting of N_{SP} super peer nodes and N_{LP} leaf peer nodes, with $N_{SP} \in [16, 25, 36, 49, 64, 81, 100, 121, 144]$, and $N_{LP} = 1000$, respectively.

The network area is supposed to be a square 1000x1000 m² large. Furthermore, LP nodes are assumed to be distributed uniformly at random, while SP nodes are assumed to be distributed

¹⁰This is typically done in peer-to-peer applications.

over a grid so that the coordinates of the i -th SP, (x_i, y_i) , are given by:

$$x_i = \begin{cases} \left(i - \lfloor \frac{i-1}{\sqrt{N_{SP}}} \rfloor \cdot \sqrt{N_{SP}} - \frac{1}{2}\right) \cdot \Delta & \forall i \in [1, N_{SP}] : \lfloor \frac{i-1}{\sqrt{N_{SP}}} \rfloor \text{ is even.} \\ s - \left(i - \lfloor \frac{i-1}{\sqrt{N_{SP}}} \rfloor \cdot \sqrt{N_{SP}} - \frac{1}{2}\right) \cdot \Delta & \forall i \in [1, N_{SP}] : \lfloor \frac{i-1}{\sqrt{N_{SP}}} \rfloor \text{ is odd.} \end{cases} \quad (3)$$

and

$$y_i = \lfloor \frac{i-1}{\sqrt{N_{SP}}} \rfloor \cdot \Delta + \frac{\Delta}{2} \quad (4)$$

where $s = 1000$ m and we set $\Delta = s/\sqrt{N_{SP}}$. As a consequence, applying eq. (1), we obtain that the identifier of the n -th SP is given by:

$$p_n = \mathcal{M}(x_n, y_n) = \left(n - \frac{1}{2}\right) \cdot \frac{1}{N_{SP}} \quad (5)$$

Furthermore, we assume that SPs p_i and p_j , with $i, j \in [1, N_{SP}]$ and $i \neq j$, located in the positions (x_i, y_i) and (x_j, y_j) , respectively, are connected by a link if and only if one of the four following conditions hold: (a) $x_i = x_j$ and $y_i = y_j + \Delta$; (b) $x_i = x_j$ and $y_i = y_j - \Delta$; (c) $x_i = x_j + \Delta$ and $y_i = y_j$; or (d) $x_i = x_j - \Delta$ and $y_i = y_j$.

In this section we will assess the WILLAGE system performance through simulations and compare it to that of other relevant solutions. More specifically, first we will focus on the performance of Georoy and compare it to Viceroy. Here the performance metrics under investigation will be the number of logical links in $P(k)$, i.e., the path traversed by a query on a generic key k in the overlay network, the number of hops in the physical network of $P(k)$, i.e., $l(P(k))$, and the stretch factor defined as in (2). Then, we will assess the WILLAGE platform in two critical cases, i.e., 1) when a leaf peer makes handoff from a SP to another; and 2) when a new resource must be added to the distributed catalog of the shared resources (or a resource must be removed from the distributed catalog of the shared resources).

Observe that both Georoy and Viceroy only consider SPs, therefore a variation in the number of LPs does not affect the performance of the algorithm. This is why the number of LPs has been assumed to be constant and equal to 1000.

In Figure 5, we compare the average number of logical links traversed by a query using Georoy and Viceroy algorithms vs. the number of SPs. Each result was obtained by averaging over 10000 simulations. As expected, Georoy and Viceroy algorithms exhibit the same behavior in terms of logical links being traversed at the overlay network level by a query on a certain resource key. This is because the only difference between Viceroy and Georoy lies in the way the overlay network is mapped into the physical network and thus there are no differences at the overlay network level. The same consideration also applies to the variance of the number of logical links traversed by a query on a certain key, as shown in Figure 6.

In Figure 7 we show the average number of hops traversed in the physical network by a query on a certain key when Georoy and Viceroy algorithms are utilized. It can be observed that the

Georoy algorithm drastically reduces the number of physical hops needed to localize the searched resource with respect to the Viceroy algorithm. This was an expected result, and is due to the mapping function used in Georoy to reduce the stretch factor.

To additionally highlight the effectiveness of Georoy when compared to Viceroy, in Figure 8 we show a comparison between the stretch factor of the two algorithms. As expected, the Viceroy algorithm has a stretch factor which can be as much as 7 times higher than that of Georoy. Once again, the reason of this has to be searched in the similarity between the overlay and the physical network obtained using the Georoy approach. In Figure 8 we also show the upper bound on the Georoy stretch factor as given in Theorem 2. Notice that the stretch factor of Viceroy is far above this bound.

We also assessed the performance of the WILLAGE platform in terms of the amount of signaling generated in two significant cases.

More specifically, in Figure 9 we show the average number of hops at the physical layer traversed by signals to update the information about the resources shared by a LP in the distributed catalog when the operations described in Section 5.2 are performed. In order to evaluate the impact of the Home SP mechanism on WILLAGE performance, in the same figure we show the signaling generated when the Home SP is not employed. As discussed in Section 5.2, the introduction of the Home SP causes further signaling during the information update phase. This is confirmed by the results reported in Figure 9; however, the Home SP mechanism allows a significant signaling decrease in in case of a LP handoff from a SP to another. This is shown in Figure 10, where we present the average signaling generated due to the event of a LP u changing its SP. In this case, the distributed hash table requires to be updated as described in Section 5.4. In Figure 10 we also show the performance results achieved when the Home SP mechanism is not used for three different values of the number of resources shared by each LP, $n^{(res)} = 5, 10$, and 20 . Results in Figure 10 show that when the Home SP mechanism is not utilized, the number of resources shared by a LP, i.e., $n^{(res)}$, has a significant impact on the amount of signaling. This is because, when the Home SP mechanism is not utilized, all the SPs that manage the location information of the migrating LP must be informed of the new location. Obviously, as the number of resources shared by the LP u increases, the number of SPs that must be informed increases as well. On the contrary, the signaling generated by LP handoff in case of WILLAGE does not depend on the number of resources shared by the LP. This property ensures the scalability of WILLAGE performance even when a very large number of resources is shared by network users. In any case, we stress that the WILLAGE platform always achieves the smallest amount of signaling with respect to the other solutions. Looking at these figures it is clear that the advantages of using the Home SP mechanism increase as $n^{(res)}$ increases.

7 Conclusions and future work

In this paper, we have introduced the WILLAGE platform for peer-to-peer resource sharing in wireless mesh community networks, we have studied the properties of one of its major building blocks (the Georoy algorithm), and verified through simulation that WILLAGE achieves the goal of enabling efficient and scalable peer-to-peer resource sharing.

There are several ways to extend the work presented in this paper, which we are currently investigating. For instance, we are considering resource replication techniques to improve resource availability, and studying which is the optimal strategy for locating resource replicas in the WILLAGE system. Also, we are considering strategies for cross-layer optimization of the Georoy algorithm which exploit the broadcast nature of the wireless communications. More work needs to be also done in the evaluation of WILLAGE's performance under highly dynamic network conditions.
